Denitrifying Bioreactor

**Definition**

The denitrifying bioreactor is a structure containing a carbon source, installed to reduce the concentration of nitrate nitrogen in subsurface agricultural drainage flow via enhanced denitrification.

**Practice Information**

The denitrifying bioreactor is one of several practices that may be used to help prevent excessive nitrate concentration in tile drainage water leaving crop fields.

Typically, the bioreactor is installed at the end of a tile system, just before the drainage water enters a drainage ditch or stream. A water control structure is installed on the tile line, and this structure allows the operator to divert some of the drainage flow to the bioreactor chamber. During periods of high flow in the tile system, the structure is set to bypass excess flow without going through the bioreactor. Since the tile does not flow full most of the time, this strategy is a good way to make sure that most of the nitrate in the tile water is removed, without negatively affecting the ability of the tile system to drain.

The bioreactor chamber is a pit excavated into the ground near the tile line. The pit is lined with plastic and filled with wood chips. The plastic is installed to keep the soil from migrating into the wood chips, and to make sure that the tile water stays in the wood chip chamber long enough to adequately remove the nitrates. The pit can be filled entirely with wood chips, or the design could include a protective layer of soil at least 2 feet deep over the wood chips, if vehicular traffic is expected over the trench.

Installation of the bioreactor involves plumbing as well as wood chips. Pipes connect the control structure in the main tile line to a distribution manifold (perforated pipe) at the beginning of the bioreactor chamber. At the other end of the chamber, a collector pipe gathers up the treated water and sends it through a structure, on out to the ditch or stream. The chips can be replaced and recycled, if necessary, to continue the process when they lose their ability to remove nitrates.

The real work in the bioreactor is accomplished by denitrifying bacteria. These organisms colonize the wood chips, using the carbon in the wood as an energy source and reducing nitrates in the water to nitrogen gas. The bioreactor is designed to last at least 10 years.
